Regional ambient temperature is associated with human personality

Human personality traits differ across geographical regions4–5. However, it remains unclear what generates these geographical personality differences. Because humans constantly experience and react to ambient temperature, we propose that temperature is a crucial environmental factor that is associated with individuals’ habitual behavioural patterns and, therefore, with fundamental dimensions of personality. To test the relationship between ambient temperature and personality, we conducted two large-scale studies in two geographically large yet culturally distinct countries: China and the United States. Using data from 59 Chinese cities (N = 5,587), multilevel analyses and machine learning analyses revealed that compared with individuals who grew up in regions with less clement temperatures, individuals who grew up in regions with more clement temperatures (that is, closer to 22 °C) scored higher on personality factors related to socialization and stability (agreeableness, conscientiousness, and emotional stability) and personal growth and plasticity (extraversion and openness to experience). These relationships between temperature clemency and personality factors were replicated in a larger dataset of 12,499 ZIP-code level locations (the lowest geographical level feasible) in the United States (N = 1,660,638). Taken together, our findings provide a perspective on how and why personalities vary across geographical regions beyond past theories (substance style theory, selective migration theory and pathogen prevalence theory). As climate change continues across the world, we may also observe concomitant changes in human personality.

A wealth of evidence suggests that human personality traits differ across geographical regions4–5. Such geographical variation in personality has been shown to predict a broad array of psychological, political, economic and health outcomes14,15. However, one important question remains: What generates these geographical differences in personality?

Humans constantly experience and react to ambient temperature. Because temperature varies markedly across the world, it is conceivable that temperature shapes the fundamental dimensions of personality by affecting the habitual behaviours that underlie personality traits. Temperature may shape personality directly by influencing individual behaviours (for example, exploring outdoors versus staying indoors), and less directly by influencing collective activities (for example, agriculture) that guide individual behaviours. Consequently, regions with different ambient temperatures may result in different patterns of personality traits.

Personality is defined as “the interactive aggregate of personal characteristics that influence an individual’s response to the environment”5. The hundreds of personality traits used to describe humans are largely captured by five broad dimensions, often called the Big Five: agreeableness, conscientiousness, emotional stability, extraversion, and openness to experience. These five personality factors can be further aggregated into two higher-order factors: ‘Alpha’ (agreeableness, conscientiousness, and emotional stability), which represents a socialization and stability factor, and ‘Beta’ (extraversion and openness to experience), which represents a personal growth and plasticity factor16,17. We propose that ambient temperature clemency is a key factor that relates to personality. This proposition is rooted in the fact that, as a warm-blooded species, humans have the existential need for thermal comfort12,13. Clement (that is, mild) temperatures encourage individuals to explore the outside environment, where both social interactions and new experiences abound; by contrast, when the ambient temperature is either too hot or too cold, individuals are less likely to go outside (for example, to meet up with friends, or to try new activities)18. This perspective is consistent with attachment theories, which state that individuals are more likely to explore their environments when they feel psychologically secure19,20.

Based on this reasoning, we hypothesize that individuals who grow up in more clement temperatures will be higher on both the socialization factor (Alpha) and the personal growth factor (Beta). Regarding the socialization factor Alpha, research has found that personality traits develop partly through social interactions11,21. More clement temperatures facilitate social contact19, for which agreeableness, conscientiousness and emotional stability are important21. Moreover, clement temperatures have been shown to enhance

positive mood\textsuperscript{22} and lead individuals to behave more prosocially\textsuperscript{23}. Regarding the personal growth factor Beta, more clement temperatures promote a wider range of activities, which may lead individuals to become more extraverted and open to new experiences\textsuperscript{24}. A study of 49 cultures revealed that the mean temperature of a cultural region was positively related to people’s perception of how extraverted and open a typical person in that culture is; however, this study did not examine how temperature was related to actual personalities beyond these stereotypical perceptions\textsuperscript{25}. In another study of 1,662 Chinese residents\textsuperscript{21}, individuals from provinces with more clement temperatures scored higher on individualism — a cultural value dimension that is positively correlated with extraversion\textsuperscript{26}.

Our temperature clemency perspective adds to several key theories that speak to geographical variation in personality\textsuperscript{27,28,29}. First, subsistence style theory posits that different subsistence strategies can produce geographical differences in personality-related cultural constructs\textsuperscript{27,29}; for example, members of farming and fishing communities, which value harmonious social interdependence, show greater holistic tendencies than members of herding communities, which value individual decision making and social independence\textsuperscript{28}. Second, the selective migration theory of personality proposes that selective migration patterns can produce geographical differences in personality. According to this view, people selectively migrate to regions that fulfill and reinforce their physical and psychological needs\textsuperscript{29}. Third, the pathogen prevalence theory of personality suggests that, as a self-protective mechanism, individuals exhibit lower extraversion and openness to experiences in regions with a higher prevalence of disease-causing pathogens\textsuperscript{29}.

There is ample evidence that ambient temperature affects agricultural activities (when and what to farm)\textsuperscript{30,31}, individuals’ migration decisions\textsuperscript{1}, and pathogen prevalence\textsuperscript{32}. Thus, ambient temperature likely has important explanatory power for geographical variation in personality. Overall, our temperature clemency perspective of personality offers a mechanism for why and how macro-level environmental forces might shape individual-level personality.

Several methodological problems have plagued the few investigations into geographical differences in personality. Most notably, previous research has largely focused on personality differences across broad geographical regions (for example, across countries)\textsuperscript{33–35}, which makes it difficult to eliminate the confounding effects of other variables, such as between-country cultural differences. To isolate the effects of ambient temperature from such confounding variables, the use of subject samples from within a single country is preferable. Of course, that single country must be of substantial geographical size to capture sufficient variance in temperature. A related issue with examining personality at the country level is that analyses at such a broad level may obscure meaningful within-country regional variances in temperature and personality. Thus, it is important to analyse the effects of temperature on personality at the lowest geographical levels feasible — that is, at the city level or even the ZIP-code level — within which variances in both temperature and personality differences will be minimal.

To overcome these methodological concerns, we conducted two separate, large-scale studies within two geographically large yet culturally distinct countries: China and the United States. Given that the period from birth to adulthood is crucial for personality development\textsuperscript{10}, for each participant, we collected meteorological data of the geographical location where he or she grew up.

In study 1, a total of 5,587 university students (42.4% females, mean age = 22.07 years, s.d. age = 2.05) who were born and raised in 59 Chinese cities completed a personality survey online in return for individualized feedback (see Supplementary Information for details). These cities covered all provincial-level administrative divisions in continental China (Fig. 1; Supplementary Table 1). To preclude reverse causality, in which certain personalities may cause individuals to migrate to cities with certain temperatures, we limited our sample to students who had spent their pre-college youth in their birthplace. To rule out another alternative explanation — that parents with certain personalities chose to migrate to a certain city and then gave birth to children who resemble their personalities — we further limited the sample to participants whose birthplace matched their ancestral home (that is, jigu, the home of their patrilineal ancestors). Importantly, all results remained substantively unchanged without these exclusion criteria.

In line with past research\textsuperscript{36–41}, we computed a ‘temperature clemency’ variable, $[\text{mean temperature} - 22{°}\text{C}]$, which measures the extent to which a city’s ambient temperature is close to the psychophysiological comfort optimum of 22 °C (about 72 °F). Thus, the further a city’s temperature is from 22 °C, the less clement it is.

At the city level, temperature clemency was positively correlated with both Alpha and Beta, as well as with each of the Big-Five personality factors ($P < 0.05$ for all personality factors except agreeableness, for which $P = 0.160$; see Supplementary Table 5). Figure 1 maps the temperature clemency of each city with Alpha and Beta, respectively. By contrast, air pressure or wind speed was not significantly correlated with Alpha, Beta or any of the Big-Five personality factors ($P > 0.23$ for all personality factors).

Because the 5,587 participants (level 1) were nested within the 59 cities (level 2), we conducted multilevel analyses to account for the statistical dependence within each city and the fact that different cities had different sample sizes (see Supplementary Tables 6–12). Consistent with the city-level correlational results, temperature clemency was positively associated with Alpha, Beta, and each of the Big-Five personality factors, even after accounting for individual-level control variables age, gender, and acquiescent response style ($P < 0.05$ for all personality factors) and city-level control variables population density, gross domestic product (GDP) per capita, average annual rice-farming area, average annual wheat-farming area, influenza incidence, and the standard deviation of the mean temperature ($P < 0.01$ for all personality factors).
As a robustness check, we also computed another version of temperature clemency using \(- (\text{minimum temperature} - 22 \degree C) + (\text{maximum temperature} - 22 \degree C)\). All results remained substantively unchanged when we used this measure as the predictor in multilevel analyses ($P<0.01$ for all personality factors) (see Supplementary Table 13). Figure 2a compares the effect sizes (calculated by t-to-r transformation) of all the predictor variables and highlights the importance of temperature clemency in the Chinese sample.

In addition to multilevel analyses, we conducted machine-learning analyses to explore which of the variables were likely important predictors of personality (see Supplementary Figs. 8–12). Consistent with the results of multilevel modelling, conditional random forest analyses reliably identified temperature clemency to be an important predictor of each of the seven personality factors. For analytical details, see Supplementary Information.

In support of our temperature clemency perspective of personality, study 1 revealed a relationship between ambient temperature clemency and personality among Chinese participants: individuals who grew up in cities with milder temperatures scored higher on both the socialization factor (Alpha) and the personal growth factor (Beta) of personality, as well as on each of the Big-Five personality factors.

Study 2 sought to extend study 1 in several important ways. First, we investigated whether the effects of temperature clemency on personality factors would replicate in the United States, another geographically large yet culturally distinct country. Second, we more closely scrutinized these effects by collecting data at the lowest geographical level feasible: the ZIP-code level. Third, to examine the robustness of these effects, we used another well-validated measure of the Big-Five personality factors (see Supplementary Information). Fourth, we used an even larger participant sample ($N = 1.6$ million) that was representative of the general US population in terms of age, social class, and education levels (age range $= 16$–60 years, as opposed to only university students)

Study 2 involved 1,660,638 Americans who participated in return for a customized personality evaluation (65.3% female, mean age $= 27.05$ years, s.d. age $= 11.00$, 17.0% with a college degree, 9.44% with a graduate degree) (for details, see Supplementary Information). Participants reported the US ZIP code where they spent most of their youth (12,499 US ZIP codes in 8,102 cities). As in study 1, we operationalized ambient temperature as being ‘more clement’ to the extent that it is closer to 22°C.

Replicating the Chinese data, multilevel analyses (see Supplementary Tables 17–23) revealed that temperature clemency was positively associated with Alpha, Beta, and each of the Big-Five personality factors after accounting for individual-level control variables age, gender, education, and acquiescent response style ($P<0.015$ for all personality factors) and ZIP-code level control variables humidity, wind speed, population density, GDP per capita, the percentages of civilians employed in the primary sector (for example, agriculture), in the secondary sector (for example, construction, and manufacturing), and in the tertiary sector (that is, service) ($P<0.001$ for all personality factors). Importantly, temperature clemency was the only meteorological variable that was consistently associated with each of the seven personality factors; for example, neither humidity nor wind speed was significantly associated with emotional stability ($P>0.25$ for both humidity and wind speed).

Figure 2b compares the effect sizes (calculated by t-to-r transformation) of all the predictor variables and highlights the importance of temperature clemency in the sample from the United States.

Consistent with the results of multilevel modelling, machine-learning analyses using conditional random forest again reliably identified temperature clemency to be an important predictor of each of the seven personality factors (see Supplementary Figs. 13–17).

In summary, two large-scale studies from China and the United States found that the ambient temperature during an individual’s youth was related to the key dimensions of personality: individuals who grew up in more clement regions scored higher on both the socialization factor (Alpha) and the personal growth factor (Beta) of personality, as well as on each of the Big-Five personality factors. These effects were robust when controlling for various factors that might affect personality-related constructs: selective migration, individual response style, demographic factors (age, gender, and education), socioeconomic factors (population density, GDP per capita, rice-farming area, and wheat-farming area), ecological factors (pathogen prevalence), and other meteorological

As a robustness check, we also computed another version of temperature clemency using \(- (\text{minimum temperature} - 22 \degree C) + (\text{maximum temperature} - 22 \degree C)\). All results remained substantively unchanged when we used this measure as the predictor in multilevel analyses ($P<0.01$ for all personality factors) (see Supplementary Table 13). Figure 2a compares the effect sizes (calculated by t-to-r transformation) of all the predictor variables and highlights the importance of temperature clemency in the Chinese sample.

In addition to multilevel analyses, we conducted machine-learning analyses to explore which of the variables were likely important predictors of personality (see Supplementary Figs. 8–12). Consistent with the results of multilevel modelling, conditional random forest analyses reliably identified temperature clemency to be an important predictor of each of the seven personality factors. For analytical details, see Supplementary Information.

In support of our temperature clemency perspective of personality, study 1 revealed a relationship between ambient temperature clemency and personality among Chinese participants: individuals who grew up in cities with milder temperatures scored higher on both the socialization factor (Alpha) and the personal growth factor (Beta) of personality, as well as on each of the Big-Five personality factors.

Study 2 sought to extend study 1 in several important ways. First, we investigated whether the effects of temperature clemency on personality factors would replicate in the United States, another geographically large yet culturally distinct country. Second, we more closely scrutinized these effects by collecting data at the lowest geographical level feasible: the ZIP-code level. Third, to examine the robustness of these effects, we used another well-validated measure of the Big-Five personality factors (see Supplementary Information). Fourth, we used an even larger participant sample ($N = 1.6$ million) that was representative of the general US population in terms of age, social class, and education levels (age range $= 16$–60 years, as opposed to only university students).

Study 2 involved 1,660,638 Americans who participated in return for a customized personality evaluation (65.3% female, mean age $= 27.05$ years, s.d. age $= 11.00$, 17.0% with a college degree, 9.44% with a graduate degree) (for details, see Supplementary Information). Participants reported the US ZIP code where they spent most of their youth (12,499 US ZIP codes in 8,102 cities). As in study 1, we operationalized ambient temperature as being ‘more clement’ to the extent that it is closer to 22°C.

Replicating the Chinese data, multilevel analyses (see Supplementary Tables 17–23) revealed that temperature clemency was positively associated with Alpha, Beta, and each of the Big-Five personality factors after accounting for individual-level control variables age, gender, education, and acquiescent response style ($P<0.015$ for all personality factors) and ZIP-code level control variables humidity, wind speed, population density, GDP per capita, the percentages of civilians employed in the primary sector (for example, agriculture), in the secondary sector (for example, construction, and manufacturing), and in the tertiary sector (that is, service) ($P<0.001$ for all personality factors). Importantly, temperature clemency was the only meteorological variable that was consistently associated with each of the seven personality factors; for example, neither humidity nor wind speed was significantly associated with emotional stability ($P>0.25$ for both humidity and wind speed).

Figure 2b compares the effect sizes (calculated by t-to-r transformation) of all the predictor variables and highlights the importance of temperature clemency in the sample from the United States.

Consistent with the results of multilevel modelling, machine-learning analyses using conditional random forest again reliably identified temperature clemency to be an important predictor of each of the seven personality factors (see Supplementary Figs. 13–17).

In summary, two large-scale studies from China and the United States found that the ambient temperature during an individual’s youth was related to the key dimensions of personality: individuals who grew up in more clement regions scored higher on both the socialization factor (Alpha) and the personal growth factor (Beta) of personality, as well as on each of the Big-Five personality factors. These effects were robust when controlling for various factors that might affect personality-related constructs: selective migration, individual response style, demographic factors (age, gender, and education), socioeconomic factors (population density, GDP per capita, rice-farming area, and wheat-farming area), ecological factors (pathogen prevalence), and other meteorological factors.
The variables to the right of the red dashed line are statistically significant in predicting personality.

Factors (air pressure, humidity, and wind speed). It is particularly telling that our large datasets from two geographically large yet culturally distinct countries provided converging evidence. Taken together, these findings are consistent with our temperature clemency perspective of personality: growing up in temperatures that are close to the psychophysiological comfort optimum encourages individuals to explore the outside environment, thereby influencing their personalities.

The present research adds to past theories and findings on how socioecological factors (selective migration, subsistence strategies and pathogen prevalence) are associated with human personality. Theoretically, we point to a probable antecedent of these factors: ambient temperature. Empirically, we explicitly controlled for selective migration, subsistence strategies, and pathogen prevalence in the Chinese sample. Moreover, whereas past studies focused on broad geographical levels (for example, countries), we examined the effects of ambient temperature on personality at the lowest geographical levels feasible (city and ZIP-code levels).

Although our temperature clemency perspective of personality offers a mechanism for why and how macro-level environmental forces might influence individual-level personality, we note that temperature clemency is one of many factors associated with human personality. In addition, standardized partial effect size plots (Fig. 2) and variable importance plots (Fig. 3; Supplementary Figs. 8–17) suggest that temperature clemency might be more associated with the personalities of Chinese individuals than the personalities of American individuals. Future research could further examine such cross-cultural differences.

In light of the present findings, it is also important to highlight social thermoregulation theory[^3][^2], which posits that people seek ‘social warmth’ in a cold environment because an important function of social relationships is to facilitate the regulation of body temperature. For example, a recent study found that, compared with residents of warmer climates, residents of colder climates reported a wider variety of social ties[^3]. Importantly, social thermoregulation theory and our temperature clemency perspective of personality do not necessarily oppose each other. Although social thermoregulation theory suggests that a cold climate compels people to seek social warmth, our findings suggest that a clement climate encourages people to explore the outside environment to engage in more social activities and new experiences that are conducive to socialization (Alpha) and growth (Beta).

While much is known about the effects of temperature on human health and performance, the present research examined its
relationship with personality. Our findings offer insights into why people in different regions of the world exhibit different personality traits and behaviours. As climate change continues across the world, we may also observe concomitant changes in human personality. Of course, questions about the size and extent of these changes await future investigation.

Methods
For analytical details of multilevel and machine-learning analyses, see Supplementary Information.

Study 1. This research was approved by the Institutional Review Board of Peking University. All participants completed the 40-item Mini-Markers Scale that assessed the Big-Five personality factors, each of which consisted of eight items (ω reliabilities = 0.79, α reliabilities = 0.84. We corrected for the standard deviation of mean temperature for each city. Finally, because temperature fluctuation might also affect personality (over and above mean temperature), we also controlled for the standard deviation of mean temperature for each city.

Study 2. This research was approved by the Institutional Review Board of the University of Texas. Each participant completed the 44-item Big-Five Inventory (ω reliabilities = 0.84, α reliabilities = 0.86. We corrected for the standard deviation of mean temperature for each city.

Life Sciences Reporting Summary. Further information on experimental design is available in the Life Sciences Reporting Summary.

Code availability. Analyses were conducted in R and Stata. All code is available upon request.

Data availability. Personality data are available from the corresponding author upon request.
